Note: After repeated attempts to finish the data capture, inexplicably the gestures I did on the website and downloaded would not be fully included in the json (often coming in unlabeled, and missing half or more of the gestures). After speaking with the professor, it was determined that I'm ok to use the data that I have incomplete as it is for the sake of completing the assignment.

The differences that I observed were that the baseline model utilized a very different style of gesturing some of the numbers. I found it particularly hard to gesture 9, taking several tries before it recognized what I thought was a very reasonable 9. Additionally, both models felt to have struggled with the number 5.

For scoring, going off the numbers, the baseline would often score higher, with the fine tuned model more often having less confident final scores for some digits. I believe this to be a consequence of the data capture problems I was experiencing, as other digits that were more accounted for in my data score similarly.

The main benefit of fine tuning was the effect of making it so that the board was able to recognize my own gestures instead of a different person's gestures more consistently, even if some weren't as high scoring. I found it resulted in a lot less attempts for each digit to be recognized, which speaks to the power of tailoring the specific recognition to the end user for ease of their use.
